AI-2 is an autoinducer made by many bacteria. LsrB binds AI-2 in the periplasm, and Tsr is the L-serine chemoreceptor. We show that AI-2 strongly attracts Escherichia coli. Both LsrB and Tsr are necessary for sensing AI-2, but AI-2 uptake is not, suggesting that LsrB and Tsr interact directly in the periplasm.

Many functions in bacteria are regulated by population density, including formation of biofilms and production of virulence factors (5). Assessment of population density, known as quorum sensing, relies on the ability of cells to determine the concentrations of compounds known as autoinducers (AIs). As the cell density increases, an AI accumulates to a concentration that triggers a quorum-sensing response. Autoinducers activate some genes and repress others. Induced genes typically include those responsible for production of the autoinducer, resulting in a positive feedback loop. Cell densities required to accumulate enough AI for good induction are $10^8$ per ml or higher.

AIs are of two basic types: species specific and general (22). Species-specific AI-1s are acyl homoserine lactones in Gram-negative bacteria and modified peptides in Gram-positive bacteria. Full induction of bioluminescence in the marine bacterium Vibrio harveyi, which colonizes dead organic matter, requires both a specific AI-1 inducer and a general autoinducer, called AI-2 (6). AI-2 is derived from spontaneous cyclization of 4,5-dihydroxy-2,3-pentanedione (DPD). DPD is made from 2-methyl-2,3,3,4-tetrahydroxytetrahydrofuran (R-THMF). R-THMF binds to the periplasmic LsrB protein (21). LsrB is the recognition component of an ABC transporter for AI-2. LsrACD are the membrane-bound components of the ABC transporter for AI-2. AI-2 is generated by the enzyme LuxS, and the YdgG (TqsA) protein has been implicated in AI-2 export from the cytoplasm (14).

AI-2 is a known chemoattractant for Escherichia coli (4, 10), but the receptor(s) involved in AI-2 sensing has not been identified. This work was initiated to characterize the proteins involved in AI-2 recognition by E. coli strain CV1, which is equivalent to the standard wild-type chemotaxis strain RP437. The strains used in this study are shown in Table 1.

The microplug (µPlug) assay (9), a modified plug-in-pond assay, provides a qualitative but highly visual representation of chemotaxis. Cells containing the green fluorescent protein (GFP)-encoding plasmid pCM18 were grown overnight at 32°C in tryptone broth (TB) containing 150 µg/ml erythromycin. Cells were back-diluted to a turbidity of 0.05 at 600 nm in 25 ml of TB lacking erythromycin and then grown in an incubator at 32°C. Cells were examined by phase-contrast microscopy to ensure robust motility and normal run-tumble swimming behavior. The cells were harvested by low-speed centrifugation at 400 g for 5 min, gently washed twice with chemotaxis buffer (CB; phosphate-buffered saline, 0.1 mM EDTA, 0.01 mM L-methionine, and 10 mM D,L-lactate) and then gently resuspended in 2 ml of CB. These cells were again examined under the microscope to ensure robust motility and normal run-tumble swimming behavior. Cells were mixed with an approximately equal number of TG1 cells expressing red fluorescent protein (RFP) from plasmid pDS-Red Express that had been killed by a 1-h treatment with 1 mg/ml kanamycin. The dead RFP-containing cells served as a control to visualize any mixing due to turbulence within the microfluidic chamber.

The responses of E. coli strain CV1 and its isogenic tsr and lsrB mutant derivatives are shown in Fig. 1. In the absence of AI-2 in the plug, CV1 cells distributed themselves randomly (Fig. 1A). However, when CV1 cells were exposed to plugs...
containing 200 μM L-serine or 200 μM AI-2, they exhibited strong attractant responses, shown by the accumulation of bacteria at the agarose plug-liquid interface (Fig. 1B and C). Strain CV5 (CV1 Δtsr), which lacks the L-serine receptor Tsr, did not respond to L-serine (Fig. 1D) and gave a severely attenuated response to AI-2 (Fig. 1E). Strain CV12 (CV1 Δtar-tap Δtrg), which has Tsr as its only functional receptor (other than Aer), responded to both L-serine and AI-2 (data not shown), although the accumulation was somewhat decreased relative to that of strain CV1. Thus, Tsr is both necessary and sufficient for good AI-2 chemotaxis in *E. coli* K-12, although there may be a small residual response in cells lacking Tsr.

Because AI-2 is known to bind to the periplasmic protein LsrB, we also looked at the responses of MJ101 (CV1 ΔlsrB Kanr) cells. These cells responded like strain CV1 to L-serine (Fig. 1F) but showed no accumulation around plugs containing 200 μM AI-2 (Fig. 1G). In contrast, MJ102 (CV1 ΔlsrC Kanr) cells, which should still produce LsrB but not be able to take up AI-2 into the cytoplasm, accumulated around plugs containing 200 μM L-serine (data not shown) or 200 μM AI-2 (Fig. 1H). The accumulation near AI-2 plugs was somewhat weaker than that of strain CV1, perhaps because of a polar effect of the ΔlsrC Kanr insertion on the downstream ΔlsrC operon (28). MJ101 cells containing

Because AI-2 is known to bind to the periplasmic protein LsrB, we also looked at the responses of MJ101 (CV1 ΔlsrB ΔKanr) cells. These cells responded like strain CV1 to L-serine (Fig. 1F) but showed no accumulation around plugs containing 200 μM AI-2 (Fig. 1G). In contrast, MJ102 (CV1 ΔlsrC ΔKanr) cells, which should still produce LsrB but not be able to take up AI-2 into the cytoplasm, accumulated around plugs containing 200 μM L-serine (data not shown) or 200 μM AI-2 (Fig. 1H). The accumulation near AI-2 plugs was somewhat weaker than that of strain CV1, perhaps because of a polar effect of the ΔlsrC ΔKanr insertion on the downstream ΔlsrC operon (28). MJ101 cells containing
plasmid pCA24N-P_{T5}\text{::}lrsB, which encodes wild-type *E. coli* LsrB, accumulated around AI-2-containing plugs about as well as MJ102 cells (data not shown) when 1 mM isopropyl β-D-1-thiogalactopyranoside (IPTG) was added to induce LsrB synthesis.

To quantify the response to AI-2 and to compare it to the response to L-serine, we performed capillary assays (1). As expected from the \(\mu\)Plug assay results, CV1 and CV12 cells accumulated in capillaries containing either L-serine or AI-2 (Fig. 2A), with the CV1 strain giving a stronger response, whereas CV5 (\(\Delta\)tar) cells did not accumulate in capillaries containing either compound. MJ101 cells (\(\text{lsrB}^{\text{Kan}}\)) responded to L-serine but not to AI-2, whereas MJ102 cells (\(\text{lsrC}^{\text{Kan}}\)) responded to both (Fig. 2B). Thus, the conclusions from the \(\mu\)Plug assay were confirmed.

By plotting the data from the capillary assay on a log-log plot, we could extrapolate a threshold concentration for both compounds in each strain (19). With L-serine, the extrapolated detection thresholds for strains CV1, CV12, and MJ101 were all in the range of \(2 \times 10^{-12}\) to \(4 \times 10^{-12}\) M for strains CV1 and MJ101. The regression lines for CV12 and MJ101 were identical. (D) Data for the responses of CV1, CV12, and MJ102 cells to AI-2, plotted on a log-log scale. The linear regressions can be extrapolated back to a threshold value. The extrapolated threshold concentrations are \(1.6 \times 10^{-11}\) for strain CV1, \(4.6 \times 10^{-12}\) M for strain CV12, and \(2.5 \times 10^{-14}\) M for strain MJ102.

To test the relative sensitivity of cells to L-serine and AI-2 in
FIG. 3. Assays of chemotactic behavior in the μFlow device. Cells were grown and prepared as for the μPlug assay, as described previously (9). The CMC was calculated according to the methods described in the text and elsewhere (10, 18). (A) Typical distribution of RFP-labeled dead cells, shown in red. The distribution of cells from one run is shown; it is typical for that found for RFP-labeled dead cells in all runs. The area occupied by dead cells is delineated by the gray bar enclosed in dashed lines. (B) Typical distribution of CV1 (wild-type) GFP-labeled cells in the absence of a chemoaffect gradient. The distribution of cells moving in the up-gradient direction beyond the “dead” zone is highlighted in green, and the distribution of cells moving in the down-gradient direction is highlighted in yellow. GFP-labeled cells remaining in the region occupied by dead cells (highlighted in red) were not included in the calculations of CMC values. (C) Typical distribution of CV1 cells in a 0-to-200 μM nonlinear gradient of L-serine. (D) Typical distribution of CV1 cells in a 0-to-200 μM nonlinear gradient of AI-2. (E) Typical distribution of CV1 cells in a 0-to-200 μM linear gradient of L-serine. (F) Typical distribution of CV1 cells in a 0-to-200 μM linear gradient of L-serine. All assays were run a minimum of three times. The CMC values obtained are indicated on each graph.
an independent assay, we employed the μFlow device (9, 10). A linear gradient was generated across the 1,050-μm width of the microfluidic observation chamber by utilizing two input channels, delivering 0 and 200 μM chemoaffecter. In the second scenario, a nonlinear gradient was generated by using five input channels to deliver 0, 0, 2, 20, and 200 μM chemoaffecter. The concentration at the entry point for the cells was 10 μM in the linear gradient and 2 μM in the nonlinear gradient, and the cells were preequilibrated with these concentrations prior to their introduction into the observation chamber. The distribution profiles of fluorescently labeled CV1 cells in l-serine and AI-2 are shown in Fig. 3. For each set of conditions, the chemotaxis migration coefficients (CMC values) (10, 18) were calculated (Fig. 3). Basically, the CMC value represents the difference in the total number of cells migrating in the up-gradient direction minus the total number of cells migrating in the down-gradient direction, with the cell values weighted by the fractional distance they moved toward a boundary. Thus, cells migrating all the way to the right or left walls of the chamber received a weighting factor of 1 or −1, respectively, cells migrating halfway to the right or left walls received weighting factors of 0.5 or −0.5, and so forth.

CV1 cells responded to nonlinear and linear gradients of AI-2 (Fig. 3D and F) with similar CMC values (0.24 and 0.25), but they responded significantly only to the nonlinear gradient of l-serine, in which the gradient is very steep at the point at which the cells enter the chamber (compare Fig. 3C and E). Even in the nonlinear gradient, the CMC value for l-serine was only 0.13, about 50% that of the CMC value for AI-2. These results are consistent with the idea that chemotaxis to AI-2 is more sensitive at higher chemoaffecter concentrations than is chemotaxis to l-serine.

We also tested the MJ102/pCA24N-pT5-ΔlcrB strain in a nonlinear AI-2 gradient in the μFlow device. It gave a CMC value of 0.18, which was lower than the value for CV1 cells in nonlinear AI-2 gradients but higher than that for CV1 cells in nonlinear gradients of l-serine. At present, we have no way of measuring periplasmic levels of LsrB, but the somewhat-attenuated response of MJ102/pCA24N-pT5-ΔlcrB cells relative to wild-type cells could reflect nonphysiological concentrations of LsrB in the complemented strain.

Preliminary evidence from μPlug assays (M. Hegde, unpublished data) suggests that the pathogenic S. Typhimurium strain 14028 also responds to AI-2 as an attractant and uses Tsr and LsrB to mediate that response. It may well be that many motile bacteria that produce the Tsr and LsrB proteins share the ability to perform chemotaxis to AI-2.

The reason why LsrB is essential for chemotaxis to AI-2 is not known. The role of LsrB in chemotaxis does not seem to be for transport of AI-2 into the cytoplasm, because strain MJ102, which carries the lsrC0KanR mutation, is defective for AI-2 transport (27) but is still able to carry out AI-2 chemotaxis. By analogy with other binding protein-dependent chemoreceptor systems, such as those for maltose-binding protein (MBP) and Tar (29), it may be that AI-2-bound LsrB assumes a conformation that enables it to interact with Tsr directly in the periplasm. Similar interactions have been postulated for the involvement of galactose-binding protein (13) and ribose-binding protein (2) with Trg in taxis to these two sugars and for dipeptide-binding protein with Tap (17). Tsr is the only one of the four canonical chemoreceptors of E. coli not known to interact with a substrate-binding protein. It may be on the verge of losing that unique status.

The typical paradigm for indirectly binding chemoreceptors is that the ligands have a micromolar $K_D$ (equilibrium dissociation constant) for the periplasmic binding protein, and the ligand-bound binding protein has a low affinity for its chemoreceptor partner, estimated at about 200 μM for MBP and Tar (29). The $K_D$ for AI-2 binding to LsrB has been reported as $\sim160$ μM (30), which is at least 100-fold higher than the $K_D$ of MBP for maltose. We do not know the levels of LsrB in the periplasm of cells grown under various conditions, but they may be significantly lower than for other binding proteins, which typically far outnumber their cognate membrane-bound transport systems and chemoreceptors. Thus, the binding affinities of AI-2 for LsrB and of AI-2-bound LsrB for Tsr could be very different than for other known indirectly binding chemoreceptors.

AI-2, unlike other known attractants for E. coli, does not serve as food for bacteria (28) but is an intraspecific and interspecific signal of cell density. Therefore, chemotaxis to AI-2 may not have the rather narrow dose-response range that is characteristic of most indirectly binding chemotaxantants (23). For nutrients, migration to concentrations higher than those needed for the maximum rate of uptake has no selective value. Given that AI-2 is produced by many different species of biofilm-forming bacteria (5), it may be that chemotaxis to AI-2 serves to recruit free-swimming, planktonic bacteria to biofilms (11). If so, there is no obvious reason why the response to AI-2 should saturate; the selective pressure may be to swim as close as possible to a source of AI-2. We are currently characterizing the molecular mechanism of AI-2 chemotaxis in order to understand how it has evolved to match the ecological context in which AI-2 chemotaxis occurs.

This work was funded in part by awards from the NSF to A.J. (CBET 0846453), the NIH (R01 GM089999) to T.K.W. and A.J., and the Bartoszek Fund for Basic Biological Science to M.D.M.

We are grateful for the Kcio strains provided by the Genome Analysis Project and the National BioResource Project (Japan): E. coli. We thank Rasika Harshey for providing S. Typhimurium strain 14028 and its Δsr derivative and Bonnie Bassler for providing S. Typhimurium strains MET 235 and MET259. Lily Bartoszek proofread the manuscript prior to submission.
